**CONTINUOUS INTERMEDIATE IMAGE CARRIER FOR AN
ELECTROPHOTOGRAPHIC PRINTER OR COPIER**

The invention concerns a continuous intermediate image carrier for an
5 electrophotographic printer or copier that serves for acquisition, transport and/or
delivery of a toner image in the electrophotographic printer copier [sic]. A
plurality of known electrophotographic printers, in particular color printers,
comprise an intermediate carrier medium, advantageously a transfer belt.
Individual color separations generated on a photoconductor with the aid of an
10 electrophotographic method are successively printed in register one atop another
from this photoconductor onto an intermediate carrier medium and are thereby
collected on the intermediate carrier medium. The color separations printed over
one another are subsequently transferred from the intermediate carrier medium
onto a carrier material to be printed. Such known intermediate carrier media are
15 typically comprised of synthetics (in particular elastomers) with a constant
electrical conductivity. These known printers are typically single sheet printers
with process speeds of < 200 DIN A4 pages per minute. Such known intermediate
carrier media are not suitable for qualitatively high-grade print results given
process speeds of > 200 pages A4 per minute.

20

The previously-known intermediate carrier media can essentially be associated into
two groups. The intermediate carrier media of the first group are high-ohmic,
whereby small transfer printing currents are required. Given small transfer
printing currents, high-voltage power supplies with low efficiency can be cost-
25 effectively used. Given these high-ohmic intermediate carrier media, the toner
transfer onto the intermediate carrier medium and from the intermediate carrier
medium also occurs with a relatively high efficiency. However, given the use of
high-ohmic intermediate carrier media it is disadvantageous that it leads to what is
known as a spraying of small characters even at relatively low process speeds,
30 whereby the print quality is reduced. Given increasing process speeds it also leads
to an electrostatic charging of the surface of the intermediate carrier medium.

- Such an electrostatic charging leads to a destruction of the print image transferred onto the intermediate carrier medium due to sporadic, uncontrollable discharges. Given these discharges what are known as Lichtenberg figures are generated via which the print image located on the intermediate carrier medium is at least
- 5 partially destroyed. The specific volume resistance determined (with the aid of a measurement arrangement described in connection with Figures 4 through 8) at 10 V measurement voltage is greater than or equal to $10^{12} \Omega \text{ cm}$ given intermediate carrier media of the first group.
- 10 Relative to the intermediate carrier media of the first group, the intermediate carrier media of the second group are relatively low-ohmic. The specific volume resistance determined (with the aid of a measurement arrangement described in connection with Figures 4 through 8) at 10 V measurement voltage is less than or equal to $10^{10} \Omega \text{ cm}$ given intermediate carrier media of the first [sic] group. Given
- 15 these intermediate carrier media the sporadic, uncontrollable discharges are in fact prevented; however, the transfer of the toner images onto the intermediate carrier medium or, respectively, from the intermediate carrier medium occurs with a relatively poor efficiency. Given low process speeds, a still-sufficient transfer of the toner images occurs via a relatively long residence time in the transfer printing
- 20 region. In printers with intermediate carrier media of the second group, it is also known to use additional wax blades and Teflon rods that contact the surface of the intermediate carrier medium in order to reduce the surface energy of the intermediate carrier medium. The adhesion forces of the toner particles on the intermediate carrier medium should thereby be reduced and the toner transfer in
- 25 the transfer printing regions should be made easier.

However, in high-capacity printers with a print capacity of > 200 sheets A4 per minute the transfer printing efficiency is significantly reduced due to the reduction of the residence time of the toner in the transfer printing regions at higher process

30 speeds. The mentioned measures for influencing the surface energy of the intermediate carrier medium then no longer lead to acceptable print results since

the service lives of the intermediate carrier media are reduced via these measures. Given a double-sided transfer printing of toner images onto carrier materials to be printed, further problems occur when the carrier material to be printed has a smaller width than the width of the intermediate carrier medium. This arrangement
5 leads to a charge carrier exchange between the intermediate carrier media directly contacting in the regions adjacent to the carrier material when a first toner image on a first intermediate carrier medium is transfer-printed onto the front side of the carrier material and a second toner image is transfer-printed from a second intermediate carrier medium onto the back side of the carrier material in a common
10 transfer printing region and the surfaces of the intermediate carrier media contact at least in one region adjacent to the carrier material. The intermediate carrier media adjacent to the carrier material are in direct contact, whereby an equalization current flows past laterally to the print substance. Due to this equalization current and the exchange of the charge carriers thereby effected given contacting of the
15 surfaces of the intermediate carrier media, an interruption of the electrical field in the transfer printing region occurs as a result of the relatively good electrical conductivity of the low-ohmic intermediate carrier media.

Known intermediate carrier media are characterized by parameters specified in
20 standards (such as, for example, ASTM D257 or IEC 60093), in particular characterized by the specific volume resistance and the specific surface resistance. It is thereby assumed that the electrical properties of the intermediate carrier material are homogeneous and exhibit no direction-dependent properties.

25 It is the object of the invention to specify an intermediate image carrier via which qualitatively high-grade print results are achieved even at relatively high process speeds.

This object is achieved via a continuous intermediate image carrier with the
30 features of the patent claim 1. Advantageous developments are specified in the dependent patent claims.

The distinctiveness of the inventive intermediate image carrier is that its electrical conductivity in the thickness direction is smaller between two measurement points that are essentially directly opposite one another than between two laterally-offset measurement points. The advantages of high-ohmic carrier materials and the advantages of low-ohmic carrier materials can thereby be combined with one another in a simple manner without the respective disadvantages arising.

The electrical conductivity between the two laterally-offset measurement points can thus be selected in a simple manner at least so high that the ignition voltage of a gas discharge is prevented between the intermediate image carrier and an image carrier from which a toner image should be transferred onto the intermediate image carrier. The electrical conductivity of the intermediate image carrier can also be selected at least so low between the two laterally-offset measurement points and at least so high between the two measurement points essentially directly opposite one another that a sufficiently-large electrical field for transfer of the toner image from the intermediate image carrier onto a final image carrier can be generated in order to achieve a high transfer printing efficiency. The electrical conductivity of the intermediate image carrier in the thickness direction between the two measurement points essentially opposite one another can also be selected in a simple manner at least so low that partial discharges on the surface of the intermediate image carrier are prevented.

An intermediate image carrier with a different electrical conductivity between the described measurement points is thus suitable to be used even in high-capacity printers with process speeds > 200 pages DIN A4 per minute and in full color printers with > 50 pages DIN A4 per minute. Qualitatively high-grade print results can then also be achieved at such high process speeds.

A second aspect of the invention concerns a continuous intermediate image carrier for a toner image in an electrophotographic printer or copier. The intermediate

image carrier comprises at least two layers, whereby a first layer arranged on the outer circumference of the intermediate image carrier has a lower conductivity than a second layer adjoining this first layer. Due to the second layer with a higher conductivity, a relatively low specific volume resistance is generated between two laterally offset measurement points that is smaller than the specific volume resistance between two opposite measurement points.

A third aspect of the invention concerns a continuous intermediate image carrier for a toner image in an electrophotographic printer or copier that comprises components with a high conductivity, which components are arranged such that the intermediate image carrier has a higher conductivity between two laterally-offset measurement points than between two essentially opposite measurement points. Via an intermediate image carrier according to the third aspect of the invention, qualitatively high-grade print results are also enabled at high process speeds > 200 sheets DIN A4 per minute.

For better understanding of the present invention, reference is made in the following to the preferred exemplary embodiments shown in the drawings, which preferred exemplary embodiments are described using specific terminology. However, it is noted that the protective scope of the invention should not thereby be limited since such variations and further modifications to the shown devices as well as such further applications of the invention as they are shown therein are viewed as typical present or future technical knowledge of a competent average man skilled in the art. The Figures show exemplary embodiments of the invention, namely:

- Figure 9 a diagram in which the requirements for the electrical conductivity of the transfer belt is shown with the aid of a representation of a

transverse resistance of the transfer belt dependent on a specific
volume resistance of the transfer belt;

Figure 10 a section of the diagram according to Figure 9, in which the
5 dependencies of the transverse resistance on the specific volume
resistance of a first transfer belt type and a second transfer belt type
are shown.

10 A schematic representation of an electrophotographic printer is shown in Figure 1,
in which elements of the printer are shown at a transfer printing point 10 for
transfer printing of toner images generated on a continuous photoconductor belt 12
onto a transfer belt 20. The photoconductor belt 12 is directed and driven via
rollers of a belt drive (not shown), of which rollers a deflection roller 14 is
arranged in a transfer printing region 10. The surface of the deflection roller 13 is
15 connected with a ground potential 15 of the printer. The ground potential is 0
volts. The photoconductor belt 20 is driven in the direction of the arrow P1 with
an essentially constant speed with the aid of a drive roller (not shown) of the belt
drive.

20 The transfer belt 20 is a continuous belt that is directed and deflected via a plurality
of rollers, whereby one of these rollers is executed as a drive roller. A first transfer
roller 16 and a second transfer roller 18 is [sic] arranged in the transfer printing
region 10 via which the transfer belt 20 is directed in the transfer printing region
10, whereby a common tangent of the first transfer roller 16 and of the second
25 transfer roller 18 on the side facing towards the deflection roller 14 intersects at
least the photoconductor belt 12, such that the transfer belt 20 passed by the
photoconductor belt 12 in the transfer printing region 10 is pressed against the
photoconductor belt 12 with a force dependent on the tension force of the transfer
belt 20.

30

The photoconductor belt 12 is charged with the aid of a charge unit (not shown), in particular with the aid of a charge corotron, whereby regions of the charged photoconductor belt 12 are subsequently discharged with the aid of a character generator (in particular an LED character generator) corresponding to the print data
5 supplied to the character generator. A charge image that corresponds to a latent print image is generated via the discharge of these regions of the photoconductor belt 12. This charge image is subsequently inked with toner material with the aid of a developer unit, advantageously via a magnetic brush, whereby a toner image 22 is generated on the photoconductor belt 12.

10

The toner image 22 is located on the surface of the photoconductor belt 12 and is transported on this into the transfer printing region 10. As already described, the deflection roller 14 has ground potential and the first transfer roller 16 and the second transfer roller 18 have a high voltage potential 26, advantageously in the
15 range of 500 to 5000 volts. The transfer of the toner image 22 from the photoconductor belt 12 onto the transfer belt 20 in the transfer printing region 10 is abetted by this potential difference, such that after the transfer of the toner image 22 onto the transfer belt 20 only toner residues are still present on the surface of the photoconductor belt 12. The photoconductor belt 12 is discharged with the aid
20 of a discharge unit after the transfer of the toner image 22. The toner residues still present on the photoconductor belt 12 are subsequently removed with the aid of a cleaning unit. A toner image already transferred onto the transfer belt 20 is designated with 24 in Figure 1. The transfer printing of the toner image 22 from the photoconductor belt 12 onto the transfer belt 20 occurs with a slight pressing
25 force with the aid of the arrangement shown in Figure 1.

A second transfer printing point of the printer for transfer printing of toner images present on transfer belts 20, 46 onto a carrier material 36 is shown in Figure 2. The transfer belt 20 is associated with a first printing group 32 for generation of print
30 images for transfer printing onto the front side of the carrier material 36. Identical elements have identical reference characters. A toner image generated with the aid

of the first printing group 32 (as described in connection with Figure 1) and transferred onto the transfer belt 20 is transported in the direction of the arrow P4 into the transfer printing region 20 shown in Figure 2. The toner images transported with the aid of the transfer belt 20 into the transfer printing region 30 are transfer-printed onto the front side of the carrier material 36 in the transfer printing region 30. In the transfer printing region 30, the transfer belt 20 is directed over a roller 38 that has a metallic roller core 40 and an electrically-conductive elastomer layer 42. The metallic roller core 40 is connected with a positive high voltage potential 44 (+HV) of approximately 3000 volts. The transfer belt 20 is a continuous belt and (as already described in connection with Figure 1) is driven in the direction of the arrow P4 with the aid of a drive roller (not shown).

The transfer belt 46 is associated with a second printing group 34 that generates toner images for printing of the back side of the carrier material 36. In the transfer printing region 30, the transfer belt 46 is directed over a roller that has a metallic roller core 50 that is connected with a negative high voltage 54 (-HV) of - [sic]approximately 3000 volts. An electrically-conductive elastomer layer 52 whose outer surface forms the roller surface surrounds the roller core 50. In the same manner as described in connection with Figure 1, a toner image is generated on the photoconductor belt with the aid of the second printing group 34, which toner image is transferred from this photoconductor belt onto the transfer belt 46.

The transfer belt 46 is driven in the direction of the arrow P5 via a drive roller (not shown). A toner image transferred onto the transfer belt 46 is transported in the direction of the arrow P5 into the transfer printing region 30 and there is transferred onto the back side of the carrier material 36. The carrier material 36 is directed and driven in the direction of the arrow P3 with the aid of roller pairs (not shown).

The drive speed of the carrier material 36 is slightly less than the revolution speed of the transfer belts 20 and 46, such that a force in the direction of the arrow P3 is exerted on the carrier material 36 in the transfer printing region 30, such that the carrier material is held taut in the region before the transfer printing region 30 and what is known as a flutter of the carrier material 36 is prevented. The carrier material 36 is advantageously a continuous paper web.

A section representation of the elements of the printer at the transfer printing point 30 is shown in Figure 3 through the section axis A-A. Identical elements have identical reference characters. As already described in connection with Figure 2, the metallic roller core 40 of the roller 38 is connected with the positive high voltage 44 (+HV) and the roller core 50 of the roller 48 is connected with negative high voltage 54 (-HV). Due to the potential difference between the positive high voltage 44 and the negative high voltage 54, a current flows through the conductive elastomer layer 42, the transfer belt 20, the carrier material 36, the transfer belt 46, the conductive elastomer layer 52 to the roller core 50 of the roller 48. The surfaces of the transfer belts 20 and 46 have direct contact in a region 60 laterally adjacent to the carrier material 36, i.e. in the direction of the roller edge of the roller 38 and the roller edge of the roller 48. As indicated by the arrow 64, a slight current thus flows transversely through the transfer belt 20 and to a contact point of the transfer belt 20 with the transfer belt 46, into the transfer belt 46 towards the roller 48.

However, as indicated by the arrow 62 the primary portion of the total current between the rollers 38 and 48 occurs through the carrier material 36. Given too-low-ohmic carrier material, the current portion (characterized by the arrow 64) of the total current would increase, whereby the current portion 62 is reduced. The transfer printing efficiency in the transfer printing of the toner images from the transfer belts 20, 46 onto the carrier material 36 thereby decreases.

The toner material present on the surface of the transfer belt 20 in the form of a toner image is shown in gap 66 and is brought into contact with the carrier material 36 by the roller 38.

5 Toner particles are located on the transfer belt 46 in the form of a toner image for printing of the back side of the carrier material 36. The toner particles on the transfer belt 46 are shown in gap 68 in Figure 3. The rollers 38 and 48 mutually serve as pressing rollers, whereby the outer sides of the transfer belts 20 and 46 are pressed against the front side or, respectively, against the back side of the carrier
10 material 36. The transfer of the toner particles from the respective transfer belt 20, 46 is at least abetted by the potential difference between the positive high voltage 44 and the negative high voltage 54. The potential difference is advantageously controlled or regulated with the aid of the total current flow between the roller core 40 and the roller core 50. According to Figure 3, the total current flow between the
15 roller cores 40 and 50 is comprised of the current flow 62 and the current flow 64.

A measurement arrangement for determination of the conductivity of the transfer belt 20 is shown in Figure 4. Naturally, conductivities of other transfer belts (in particular of the transfer belt 46) can also be determined with the aid of the
20 measurement arrangement shown in Figure 4. The measurement device 70 has an upper contact arrangement 72 with contact elements A1 and B1. A lower contact arrangement 74 is also provided that comprises the contacts A2 and B2. The contacts A1, B1, A2 and B2 respectively have a quadratic contact surface of 20 x 20 mm associated with the transfer belt 20. The contact surfaces comprise
25 stainless steel. The contact surfaces of the contacts A1 and A2 essentially congruently oppose another on opposite sides of the transfer belt 20. The contact surfaces of the contacts B1 and B2 are arranged in the same manner on opposite sides of the transfer belt 20. The contact surfaces of the contacts B1 and B2 also essentially oppose one another. The separation between the contacts A1 and B2 as
30 well as between the contacts A2 and B2 is 10 mm. The contacts A1 and B1 are pressed against the contacts A2 and B2 with a force of 55 N, whereby the contact

surfaces of the contacts A1 and B1 as well as A2 and B2 are respectively pressed against the front side or, respectively, the back side of the transfer belt 20 with a force of 55 N.

5 A section of the transfer belt 20 on which the contact surfaces of the contacts A1 and B1 are represented by a solid line is shown in Figure 5. As already described in connection with Figure 4, the contacts A1, B1, A2 and B2 respectively have a quadratic base of 20 x 20 mm. The contacts are also arranged at a separation of 10 mm.

10

A section representation through the measurement device 70 according to Figure 4 is shown in Figure 6, whereby the conductivity of the transfer belt 20 between the contact surfaces of the contacts A1 and B1 is determined. The conductivity between two points on the surface of the transfer belt 20 in its circumferential direction is thus determined with the aid of this measurement. Alternatively, the conductivity between two points on the surface of the transfer belt 20 transverse to its circumferential direction or at an angle to its circumferential direction can also be determined.

15 20 The section representation of the measurement device 70 according to Figure 6 is shown in Figure 7, whereby the conductivity of the transfer belt in the thickness direction (and thus the specific volume resistance of the transfer belt 20) is determined between the contact surfaces of the contacts B1 and B2.

25 The section representation of the measurement arrangement is shown in Figure 8 similar to Figures 6 and 7. The conductivity of the transfer belt between the two laterally offset contact surfaces of the contacts A1 and B2 is determined with the aid of the shown measurement arrangement. The resistance determined (with the aid of this measurement arrangement) between the contact surfaces of the contacts A1 and B2, corresponding to the conductivity, is also designated in this patent application as a transverse resistance. This transverse resistance is decisive for the

30

electrical properties of a transfer belt 20 in an electrophotographic printer with high print speed in order to prevent the disadvantages occurring in the prior art. The effects of the transverse resistance on the electrophotographic process in the printer are subsequently explained in further detail in connection with Figures 9
5 and 10.

Alternative to the described measurement arrangement, the sizes and separations as well as the contact materials of the contacts A1, B1, A2 and B2 can be varied.

10 In Figure 9 a diagram is shown in which the dependency of the transverse resistance of the transfer belt 20 on its specific volume resistance is specified. The target range (identified with the aid of a thick dash-dot line) comprises resistance ratios of the transverse resistance and specific volume resistance that an inventive transfer belt 20 should ideally have. However, the invention is not limited to this
15 value range. Given a direct voltage of 800 volts, the transverse resistance between the contact surfaces of the contacts A1 and B2 has been determined with the measurement arrangement according to Figure 8. The specific volume resistance between the contact surfaces B1 and B2 has been determined with the measurement arrangement according to Figure 7 given a measurement voltage of
20 10 volts direct voltage.

Given a transverse resistance of $< 4 \cdot 10^7 \Omega$, the transfer printing efficiency in the transfer printing of the toner image from the transfer belt 20 onto the carrier material 36 decreases such that only a part of the carrier material is transfer-
25 printed. A toner image with only insufficient inking on the carrier material 36 is thereby generated. The toner material remaining on the transfer belt 20 must also be cleaned from this. If the entire toner material remaining on the transfer belt 20 cannot be removed with the aid of the cleaning device provided to clean the transfer belt 20, given subsequent print images these toner residues are possibly
30 transfer-printed onto the carrier material 36, whereby only low-grade print images or maculature is [sic] generated

If the transverse resistance of the transfer belt 20 is, however, greater than $4 \cdot 10^8 \Omega$, the danger of electrical discharges (what are known as air breakdowns) is present in the transfer printing region 10 given transfer printing of the toner images from the photoconductor belt 12 onto the transfer belt 20. These electrical discharges primarily occur in the region after the contact point of both belts, i.e. of the photoconductor belt 12 and the transfer belt 20. This region is also designated as a runout gap of the transfer printing region 10. As already described, the high voltage for generation of the potential difference in the transfer printing region 10 is set based on the transfer printing current flowing between the ground potential 15 and the high voltage 26. Given high transverse resistance, a relatively high high voltage will thus be set in order to set the transfer printing current to the necessary preset value. Given resistance values of the transverse resistance $> 4 \cdot 10^8 \Omega$, however, in printers of this exemplary embodiment what is known as the Paschen curve is typically exceeded and gas discharges occur in the runout gap.

Given a specific volume resistance of $< 4 \cdot 10^{10} \Omega$, the transfer printing efficiency is likewise too low given transfer printing of the toner images from the transfer belt 20 or, respectively, 46 onto the carrier material 36. The same disadvantageous effects as already described further above in connection with a too-low transverse resistance of the transfer belt 20 thereby occur.

Given a specific volume resistance of $> 8 \cdot 10^{11} \Omega$, the danger exists that gas discharges and electrical flashovers occur in the transfer printing region 30 given the transfer printing of the toner images located on the transfer belts 20 and 46 onto the carrier material 36, whereby what are known as Lichtenberg figures arise in the toner images transfer-printed onto the carrier material 36, which Lichtenberg figures are visible in a subsequent fixed print image and significantly degrade the print quality of the print image.

The properties of the transverse resistance and of the specific volume resistance of various tested materials are plotted in Figure 10. The transfer belts used in known printers thereby form a first material group that is represented as a dashed line in the diagram according to Figure 10. The dashed line thereby indicates a linearized curve that has been determined from a plurality of measurement values of different transfer belts of the prior art. The resistance ratios of the transverse resistances and of the specific volume resistances of transfer belts 20, 46 of a second material group that have inventively isotropic material properties have been plotted linearized with the aid of a dotted line in the diagram according to Figure 10. The electrical conductivity of the transfer belts 20, 46 of the second material group is significantly less in the thickness direction between two measurement points that are essentially directly opposite than between two laterally-offset measurement points. In testing by the applicable with a specific printer type, it has emerged that the materials whose ratio of transverse resistance to specific volume resistance are [sic] arranged in the range 80 enclosed by a solid line in the diagram according to Figure 10 are particularly suitable. Excellent print results have been achieved with these transfer belts 20, 46, even at high process speeds > 200 sheets DIN A4 per minute.

According to the invention it is thus advantageous to use defined, anisotropic conductive materials as a transfer belt 20, 36. A high print quality is [sic], even at high process speeds as well as in duplex printing, in particular via the selection of a suitable transit resistance in the thickness direction, i.e. via the selection of the specific volume resistance and the selection of a suitable transverse resistance. An optimal print quality and a high rotary piston efficiency is ensured even at high process speeds and given the use of paper webs or individual sheets of varying width. The specific volume resistance is advantageously in the range from $4 \cdot 10^{10} \Omega\text{cm}$ to $8 \cdot 10^{11} \Omega\text{cm}$, which has been determined given a measurement voltage of 10 volts. The transverse resistance advantageously lies in a range between $4 \cdot 10^7 \Omega\text{cm}$ to $4 \cdot 10^8 \Omega\text{cm}$, which has been determined given a measurement voltage of 800 volts.

The transfer belts 20, 46 are advantageously continuous belts with a thickness between 50 μm and 1000 μm given a length of 1000 mm to 30000 mm and a width in the range between 100 mm and 1000 mm. The transfer belts 20, 46 comprise an electrically-insulating synthetic in which are dispersed conductive particles (such as, for example, carbon black or metallic material. Ionic conductive additives such as, for example, salts or conductive synthetics (in particular polyaniline) can alternatively or additionally be introduced into the insulating elastomer. These particles are then introduced into the base material 10 with a suitable distribution, aligned and agglomerated [sic] that the transfer belt 20, 46 has the desired anisotropic properties. The insulating synthetic can, for example, be an elastomer.

Alternatively, the transfer belt 20, 46 can also be produced from a plurality of layers of various synthetics with different conductivity. The layers advantageously run parallel to the surface of the transfer belt 20, 46.

The desired anisotropic electrical properties of the transfer belt 20, 46 can be generated via the combination of synthetic layers with different slice thickness and conductivities. The individual layers can thereby also be produced from isotropic conductive synthetics with suitable specific volume resistances. A transfer belt 20, 46 with the desired anisotropic electrical properties can be generated in a simple manner via the combination of these individual synthetic layers with different conductivity. Alternatively, at least one of the synthetic layers can have anisotropic electrical properties. In other embodiments it is also possible that all synthetic layers have anisotropic electrical properties. The individual layers can also be produced from isotropic conductive elastomers, whereby an anisotropic total composite of the transfer belt 20, 46 is generated given a suitable selection of suitable conductivities and layer thicknesses of the individual layers.

Although preferred exemplary embodiments have been shown and described in detail in the drawings and in the preceding specification, they should be viewed as

purely exemplary and not as limiting the invention. It is noted that only the preferred exemplary embodiments are shown and described, and all variations and modifications that presently or in the future lie within the protective scope of the invention should be protected.
